Ultralow Distortion, Ultralow Noise Op Amp

AD797*

FEATURES

Low Noise
- 0.9 nV/√Hz typ (1.2 nV/√Hz max) Input Voltage Noise at 1 kHz
- 50 nV p-p Input Voltage Noise, 0.1 Hz to 10 Hz

Low Distortion
- –120 dB Total Harmonic Distortion at 20 kHz

Excellent AC Characteristics
- 800 ns Settling Time to 16 Bits (10 V Step)
- 110 MHz Gain Bandwidth (G = 1000)
- 8 MHz Bandwidth (G = 10)
- 280 kHz Full Power Bandwidth at 20 V p-p
- 20 V/μs Slew Rate

Excellent DC Precision
- 80 μV max Input Offset Voltage
- 1.0 μV/°C V_{OS} Drift

Specified for ±5 V and ±15 V Power Supplies

High Output Drive Current of 50 mA

APPLICATIONS

Professional Audio Preamplifiers

IR, CCD, and Sonar Imaging Systems

Spectrum Analyzers

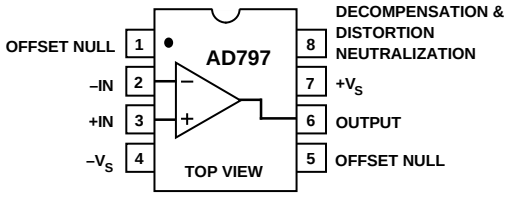
Ultrasound Preamplifiers

Seismic Detectors

ΣΔ ADC/DAC Buffers

CONNECTION DIAGRAM

8-Pin Plastic Mini-DIP (N), Cerdip (Q) and SOIC (R) Packages



PRODUCT DESCRIPTION

The AD797 is a very low noise, low distortion operational amplifier ideal for use as a preamplifier. The low noise of 0.9 nV/√Hz and low total harmonic distortion of –120 dB at audio bandwidths give the AD797 the wide dynamic range necessary for preamps in microphones and mixing consoles. Furthermore, the AD797's excellent slew rate of 20 V/μs and 110 MHz gain bandwidth make it highly suitable for low frequency ultrasound applications.

The AD797 is also useful in IR and Sonar Imaging applications where the widest dynamic range is necessary. The low distortion and 16-bit settling time of the AD797 make it ideal for buffering the inputs to ΣΔ ADCs or the outputs of high resolution DACs especially when they are used in critical applications such as seismic detection and spectrum analyzers. Key features such as a 50 mA output current drive and the specified power supply voltage range of ±5 to ±15 volts make the AD797 an excellent general purpose amplifier.

NOTES

[1]Stresses above those listed under "Absolute Maximum Ratings" may cause permanent damage to the device. This is a stress rating only, and functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

[2]Internal Power Dissipation:
8-Pin SOIC = 0.9 Watts $(T_A–25°C)/\theta_{JA}$
8-Pin Plastic DIP and Cerdip = 1.3 Watts – $(T_A–25°C)/\theta_{JA}$
Thermal Characteristics
8-Pin Plastic DIP Package: θ_{JA} = 95°C/W
8-Pin Cerdip Package: θ_{JA} = 110°C/W
8-Pin Small Outline Package: θ_{JA} = 155°C/W

[3]The AD797's inputs are protected by back-to-back diodes. To achieve low noise, internal current limiting resistors are not incorporated into the design of this amplifier. If the differential input voltage exceeds ±0.7 V, the input current should be limited to less than 25 mA by series protection resistors. Note, however, that this will degrade the low noise performance of the device.

ESD SUSCEPTIBILITY

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 volts, which readily accumulate on the human body and on test equipment, can discharge without detection. Although the AD797 features proprietary ESD protection circuitry, permanent damage may still occur on these devices if they are subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid any performance degradation or loss of functionality.

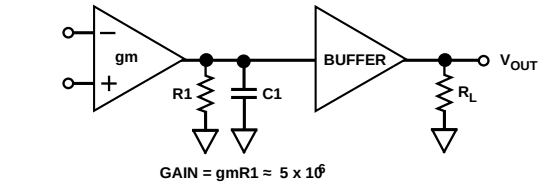
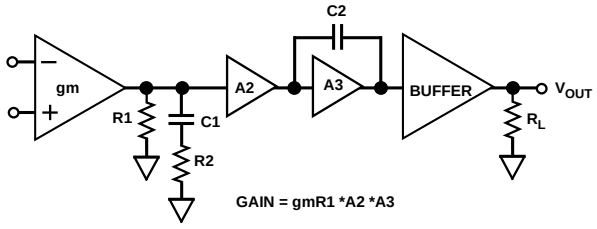
THEORY OF OPERATION

The new architecture of the AD797 was developed to overcome inherent limitations in previous amplifier designs. Previous precision amplifiers used three stages to ensure high open-loop gain, Figure 27b, at the expense of additional frequency compensation components. Slew rate and settling performance are usually compromised, and dynamic performance is not adequate beyond audio frequencies. As can be seen in Figure 27b, the first stage gain is rolled off at high frequencies by the compensation network. Second stage noise and distortion will then appear at the input and degrade performance. The AD797 on the other hand, uses a single ultrahigh gain stage to achieve dc as well as dynamic precision. As shown in the simplified schematic (Figure 28), nodes A, B, and C all track in voltage forcing the operating points of all pairs of devices in the signal path to match. By exploiting the inherent matching of devices fabricated on the same IC chip, high open-loop gain, CMRR, PSRR, and low V_{OS} are all guaranteed by pairwise device *matching* (i.e., NPN to NPN & PNP to PNP), and not absolute parameters such as beta and early voltage.



a.



b.

Figure 27. Model of AD797 vs. That of a Typical Three-Stage Amplifier

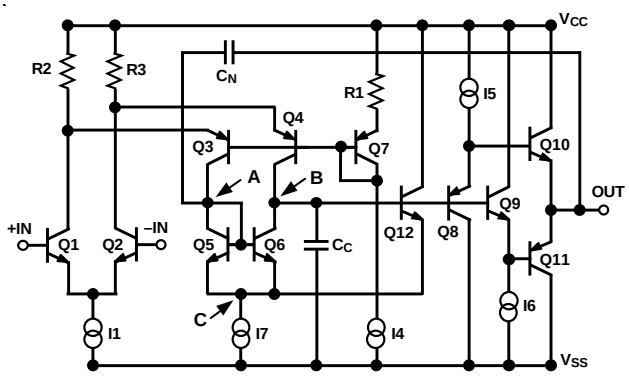


Figure 28. AD797 Simplified Schematic

This matching benefits not just dc precision but since it holds up dynamically, both distortion and settling time are also reduced. This single stage has a voltage gain of $>5 \times 10^6$ and V_{OS} <80 μV, while at the same time providing THD + noise of less than –120 dB and true 16 bit settling in less than 800 ns. The elimination of second stage noise effects has the additional benefit of making the low noise of the AD797 (<0.9 nV/√Hz) extend to beyond 1 MHz. This means new levels of performance for sampled data and imaging systems. All of this performance as well as load drive in excess of 30 mA are made possible by Analog Devices' advanced Complementary Bipolar (CB) process.

Another unique feature of this circuit is that the addition of a single capacitor, C_N (Figure 28), enables cancellation of distortion due to the output stage. This can best be explained by referring to a simplified representation of the AD797 using idealized blocks for the different circuit elements (Figure 29).

A single equation yields the open-loop transfer function of this amplifier, solving it (at Node B) yields:

$$\frac{V_O}{V_{IN}} = \frac{gm}{\frac{C_N}{A} j\omega - C_N\ j\omega - \frac{C_C}{A} j\omega}$$

gm = the transconductance of Q1 and Q2
A = the gain of the output stage, (~1)
V_O = voltage at the output
V_{IN} = differential input voltage

When C_N is equal to C_C this gives the ideal single pole op amp response:

$$\frac{V_O}{V_{IN}} = \frac{gm}{j\omega C}$$

The terms in A, which include the properties of the output stage such as output impedance and distortion, cancel by simple subtraction, and therefore the distortion cancellation does not affect the stability or frequency response of the amplifier. With only 500 μA of output stage bias the AD797 delivers a 1 kHz sine wave into 600 Ω at 7 V rms with only 1 ppm of distortion.

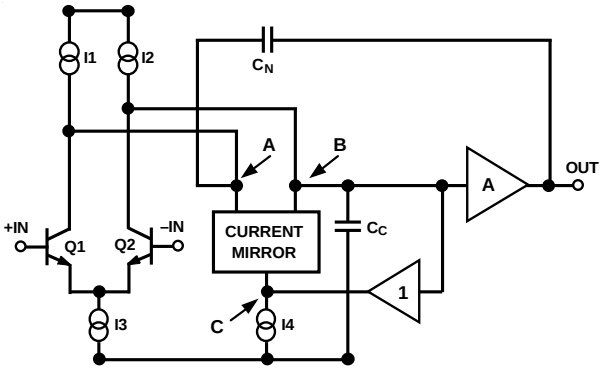

Figure 29. AD797 Block Diagram

NOISE AND SOURCE IMPEDANCE CONSIDERATIONS

The AD797's ultralow voltage noise of 0.9 nV/√Hz is achieved with special input transistors running at nearly 1 mA of collector current. It is important then to consider the total input referred noise ($e_N total$), which includes contributions from voltage noise (e_N), current noise (i_N), and resistor noise ($\sqrt{4\ kTr_S}$).

$$e_N total = [e_N^2 + 4\ kTr_S + 4\ (i_N r_S)^2]^{1/2} \qquad \text{Equation 1}$$

where r_S = total input source resistance.

This equation is plotted for the AD797 in Figure 30. Since optimum dc performance is obtained with matched source resistances, this case is considered even though it is clear from Equation 1 that eliminating the balancing source resistance will lower the total noise by reducing the total r_S by a factor of two.

At very low source resistance (r_S <50 Ω), the amplifiers' voltage noise dominates. As source resistance increases the Johnson noise of r_S dominates until at higher resistances (r_S >2 kΩ) the current noise component is larger than the resistor noise.

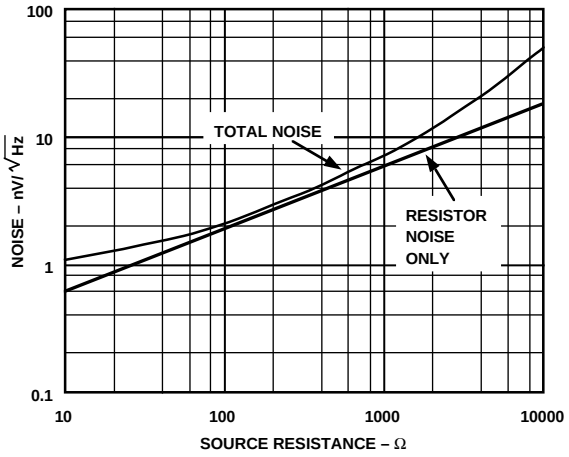

Figure 30. Noise vs. Source Resistance

The AD797 is the optimum choice for low noise performance provided the source resistance is kept <1 kΩ. At higher values of source resistance, optimum performance with respect to noise alone is obtained with other amplifiers from Analog Devices (see Table I).

Table I. Recommended Amplifiers for Different Source Impedances

r_S, ohms	Recommended Amplifier
0 to <1 k	AD797
1 k to <10 k	AD707, AD743/AD745, OP27/OP37, OP07
10 k to <100 k	AD705, AD743/AD745, OP07
>100 k	AD548, AD549, AD645, AD711, AD743/AD745

LOW FREQUENCY NOISE

Analog Devices specifies low frequency noise as a peak to peak (p-p) quantity in a 0.1 Hz to 10 Hz bandwidth. Several techniques can be used to make this measurement. The usual technique involves amplifying, filtering, and measuring the amplifiers noise for a predetermined test time. The noise bandwidth of the filter is corrected for and the test time is carefully controlled since the measurement time acts as an additional low frequency roll-off.

The plot in Figure 4 was made using a slightly different technique. Here an FFT based instrument (Figure 31) is used to generate a 10 Hz "brickwall" filter. A low frequency pole at 0.1 Hz is generated with an external ac coupling capacitor, the instrument being dc coupled.

Several precautions are necessary to get optimum low frequency noise performance:

1. Care must be used to account for the effects of r_S, even a 10 Ω resistor has 0.4 nV/√Hz of noise (an error of 9% when root sum squared with 0.9 nV/√Hz).
2. The test set up must be fully warmed up to prevent e_{OS} drift from erroneously contributing to input noise.
3. Circuitry must be shielded from air currents. Heat flow out of the package through its leads creates the opportunity for a thermoelectric potential at every junction of different metals. Selective heating and cooling of these by random air currents will appear as 1/f noise and obscure the true device noise.
4. The results must be interpreted using valid statistical techniques.

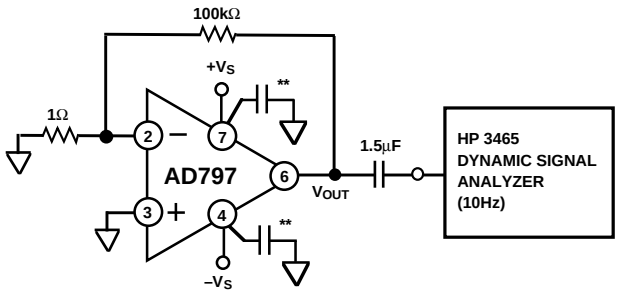

Figure 31. Test Setup for Measuring 0.1 Hz to 10 Hz Noise

WIDEBAND NOISE

The AD797, due to its single stage design, has the property that its noise is flat over frequencies from less than 10 Hz to beyond 1 MHz. This is not true of most dc precision amplifiers where second stage noise contributes to input referred noise beyond the audio frequency range. The AD797 offers new levels of performance in wideband imaging applications. In sampled data systems, where aliasing of out of band noise into the signal band is a problem, the AD797 will out perform all previously available IC op amps.

BYPASSING CONSIDERATIONS

To take full advantage of the very wide bandwidth and dynamic range capabilities of the AD797 requires some precautions. First, multiple bypassing is recommended in any precision application. A 1.0 µF–4.7 µF tantalum in parallel with 0.1 µF ceramic bypass capacitors are sufficient in most applications. When driving heavy loads a larger demand is placed on the supply bypassing. In this case selective use of larger values of tantalum capacitors and damping of their lead inductance with small value (1.1 Ω to 4.7 Ω) carbon resistors can be an improvement. Figure 32 summarizes bypassing recommendations. The symbol (**) is used throughout this data sheet to represent the parallel combination of a 0.1 µF and a 4.7 µF capacitor.

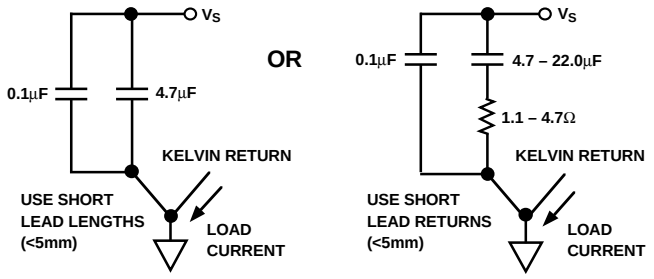

Figure 32. Recommended Power Supply Bypassing

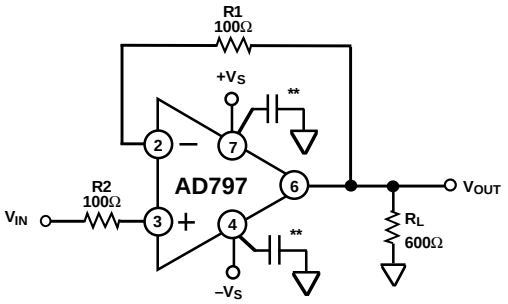
THE NONINVERTING CONFIGURATION

Ultralow noise requires very low values of r_{BB}' (the internal parasitic resistance) for the input transistors (≈6 Ω). This implies very little damping of input and output reactive interactions. With the AD797, additional input series damping is required for stability with direct input to output feedback. A 100 Ω resistor in the inverting input (Figure 33) is sufficient; the 100 Ω balancing resistor (R2) is recommended, but is not required for stability. The noise penalty is minimal (e_N*total* ≈2.1 nV/√Hz), which is usually insignificant. Best response flatness is obtained with the addition of a small capacitor (C_L < 33 pF) in parallel with the 100 Ω resistor (Figure 34). The input source resistance and capacitance will also affect the response slightly and experimentation may be necessary for best results.



** USE POWER SUPPLY BYPASSING SHOWN IN FIGURE 32.

Figure 33. Voltage Follower Connection

Low noise preamplification is usually done in the noninverting mode (Figure 35). For lowest noise the equivalent resistance of the feedback network should be as low as possible. The 30 mA minimum drive current of the AD797 makes it easier to achieve this. The feedback resistors can be made as low as possible with due consideration to load drive and power consumption. Table II gives some representative values for the AD797 as a low noise follower. Operation on 5 volt supplies allows the use of a 100 Ω or less feedback network (R1 + R2). Since the AD797 shows no unusual behavior when operating near its maximum rated current, it is suitable for driving the AD600/AD602 (Figure 47) while preserving their low noise performance.

Optimum flatness and stability at noise gains >1 sometimes requires a small capacitor (C_L) connected across the feedback resistor (R1, Figure 35). Table II includes recommended values of C_L for several gains. In general, when R2 is greater than 100 Ω and C_L is greater than 33 pF, a 100 Ω resistor should be placed in series with C_L. Source resistance matching is assumed, and the AD797 should never be operated with unbalanced source resistance >200 kΩ/G.

Gain	R1	R2	C_L	Noise (Excluding r_S)
2	1 kΩ	1 kΩ	≈20 pF	3.0 nV/√Hz
2	300 Ω	300 Ω	≈10 pF	1.8 nV/√Hz
10	33.2 Ω	300 Ω	≈5 pF	1.2 nV/√Hz
20	16.5 Ω	316 Ω		1.0 nV/√Hz
>35	10 Ω	(G–1) • 10 Ω		0.98 nV/√Hz

The I-to-V converter is a special case of the follower configuration. When the AD797 is used in an I-to-V converter, for instance as a DAC buffer, the circuit of Figure 36 should be used. The value of C_L depends on the DAC and again, if C_L is

Figure 36. I-to-V Converter Connection

greater than 33 pF a 100 Ω series resistor is required. A bypassed balancing resistor (R_S and C_S) can be included to minimize dc errors.

THE INVERTING CONFIGURATION

The inverting configuration (Figure 37) presents a low input impedance, R1, to the source. For this reason, the goals of both low noise and input buffering are at odds with one another. Nonetheless, the excellent dynamics of the AD797 will make it the preferred choice in many inverting applications, and with careful selection of feedback resistors the noise penalties will be minimal. Some examples are presented in Table II and Figure 37.

–10	150 Ω	1500 Ω	≈5 pF	1.8 nV/√Hz

DRIVING CAPACITIVE LOADS

The capacitive load driving capabilities of the AD797 are displayed in Figure 38. At gains over 10 usually no special precautions are necessary. If more drive is desirable the circuit in Figure 39 should be used. Here a 5000 pF load can be driven cleanly at any noise gain ≥ 2.

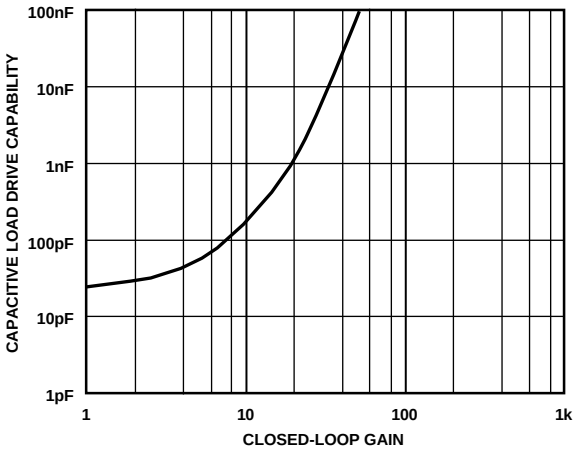

Figure 38. Capacitive Load Drive Capability vs. Closed Loop Gain

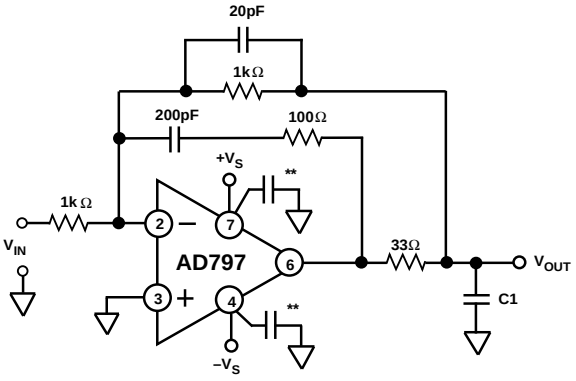

** USE POWER SUPPLY BYPASSING SHOWN IN FIGURE 32.

Figure 39. Recommended Circuit for Driving a High Capacitance Load

SETTLING TIME

The AD797 is unique among ultralow noise amplifiers in that it settles to 16 bits (<150 μV) in less than 800 ns. Measuring this performance presents a challenge. A special test setup (Figure 40) was developed for this purpose. The input signal was obtained from a resonant reed switch pulse generator, available from Tektronix as calibration Fixture No. 067-0608-00. When open, the switch is simply 50 Ω to ground and settling is purely a passive pulse decay and inherently flat. The low repetition rate signal was captured on a digital oscilloscope after being amplified and clamped twice. The selection of plug-in for the oscilloscope was made for minimum overload recovery.

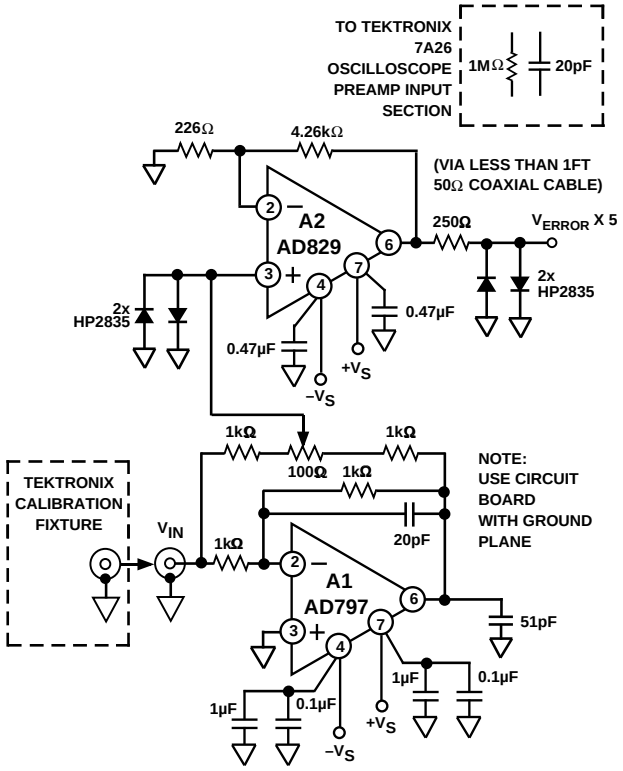

Figure 40. Settling Time Test Circuit

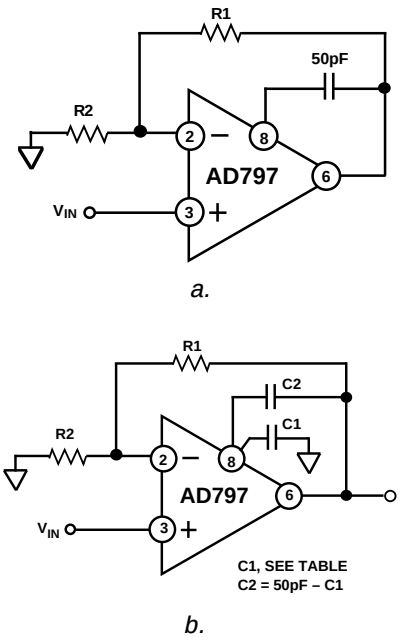

Figure 41. Recommended Connections for Distortion Cancellation and Bandwidth Enhancement

DISTORTION REDUCTION

The AD797 has distortion performance (THD < –120 dB, @ 20 kHz, 3 V rms, R_L = 600 Ω) unequaled by most voltage feedback amplifiers.

At higher gains and higher frequencies THD will increase due to reduction in loop gain. However in contrast to most conventional voltage feedback amplifiers the AD797 provides two effective means of reducing distortion, as gain and frequency are increased; cancellation of the output stage's distortion and gain bandwidth enhancement by decompensation. By applying these techniques gain bandwidth can be increased to 450 MHz at G = 1000 and distortion can be held to –100 dB at 20 kHz for G = 100.

The unique design of the AD797 provides for cancellation of the output stage's distortion (patent pending). To achieve this a capacitance equal to the effective compensation capacitance, usually 50 pF, is connected between Pin 8 and the output (C2 in Figure 41). Use of this feature will improve distortion performance when the closed loop gain is more than 10 or when frequencies of interest are greater than 30 kHz.

Bandwidth enhancement via decompensation is achieved by connecting a capacitor from Pin 8 to ground (C1 in Figure 41) effectively subtracting from the value of the internal compensation capacitance (50 pF), yielding a smaller effective compensation capacitance and, therefore, a larger bandwidth. The benefits of this begin at closed loop gains of 100 and up. A maximum value of ≈33 pF at gains of 1000 and up is recommended. At a gain of 1000 the bandwidth is 450 kHz.

Table IV and Figure 42 summarize the performance of the AD797 with distortion cancellation and decompensation.

Table IV. Recommended External Compensation

	A/B		A			B		
	R1 Ω	R2 Ω	C1 (pF)	C2 (pF)	3 dB BW	C1 (pF)	C2 (pF)	3 dB BW
G = 10	909	100	0	50	6 MHz	0	50	6 MHz
G = 100	1 k	10	0	50	1 MHz	15	33	1.5 MHz
G = 1000	10 k	10	0	50	110 kHz	33	15	450 kHz

Differential Line Receiver

The differential receiver circuit of Figure 43 is useful for many applications from audio to MRI imaging. It allows extraction of a low level signal in the presence of common-mode noise. As shown in Figure 44, the AD797 provides this function with only 9 nV/√Hz noise at the output. Figure 45 shows the AD797's 20-bit THD performance over the audio band and 16-bit accuracy to 250 kHz.

A General Purpose ATE/Instrumentation Input/Output Driver

The ultralow noise and distortion of the AD797 may be combined with the wide bandwidth, slew rate, and load drive of a current feedback amplifier to yield a very wide dynamic range general purpose driver. The circuit of Figure 46 combines the AD797 with the AD811 in just such an application. Using the

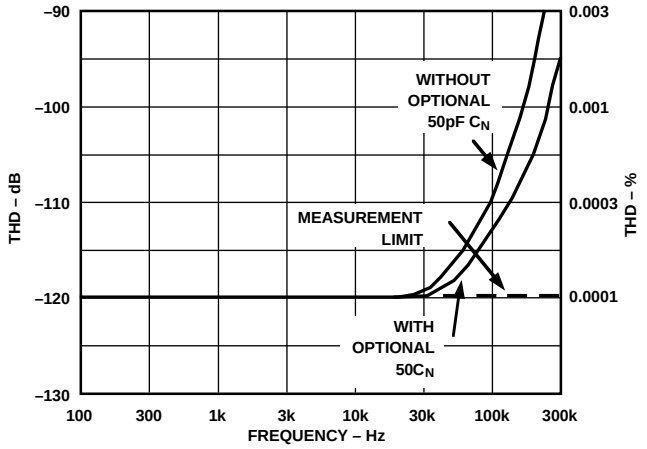

Figure 45. Total Harmonic Distortion (THD) vs. Frequency for Differential Line Receiver

component values shown, this circuit is capable of better than –90 dB THD with a ±5 V, 500 kHz output signal. The circuit is therefore suitable for driving high resolution A/D converters and as an output driver in automatic test equipment (ATE) systems. Using a 100 kHz sine wave, the circuit will drive a 600 Ω load to a level of 7 V rms with less than –109 dB THD, and a 10 kΩ load at less than –117 dB THD.

Ultrasound/Sonar Imaging Preamp

The AD600 variable gain amplifier provides the time controlled gain (TCG) function necessary for very wide dynamic range sonar and low frequency ultrasound applications. Under some circumstances, it is necessary to buffer the input of the AD600 to preserve its low noise performance. To optimize dynamic range this buffer should have at most 6 dB of gain. The combination of low noise and low gain is difficult to achieve. The input buffer circuit shown in Figure 47 provides 1 nV/$\sqrt{\text{Hz}}$ noise performance at a gain of two (dc to 1 MHz) by using 26.1 Ω resistors in its feedback path. Distortion is only –50 dBc @ 1 MHz at a 2 volt p-p output level and drops rapidly to better than –70 dBc at an output level of 200 mV p-p.

Amorphous (Photodiode) Detector

Large area photodiodes $C_S \geq 500$ pF and certain image detectors (amorphous Si), have optimum performance when used in conjunction with amplifiers with very low voltage rather than very low current noise. Figure 48 shows the AD797 used with an amorphous Si (C_S = 1000 pF) detector. The response is adjusted for flatness using capacitor C_L, while the noise is dominated by voltage noise amplified by the ac noise gain. The 797's excellent input noise performance gives 27 μV rms total noise in a 1 MHz bandwidth, as shown by Figure 49.

Professional Audio Signal Processing—DAC Buffers

The low noise and low distortion of the AD797 make it an ideal choice for professional audio signal processing. An ideal I-to-V converter for a current output DAC would simply be a resistor to ground, were it not for the fact that most DACs do not operate linearly with voltage on their output. Standard practice is to operate an op amp as an I-to-V converter creating a virtual ground at its inverting input. Normally, clock energy and current steps must be absorbed by the op amp's output stage. However, in the configuration of Figure 50, Capacitor C_F shunts high frequency energy to ground, while correctly reproducing the desired output with extremely low THD and IMD.
